Dental Pulp Revascularization in a Replanted Avulsed Immature Maxillary Permanent Central Incisor

Peter M. DI FIORE, Gary R. HARTWELL

ABSTRACT

An 8-year-old girl sustained an accidental traumatic avulsion of her right maxillary permanent central incisor. She arrived with her mother at a hospital dental clinic with the right maxillary central incisor tooth wrapped in a wet paper towel over 1 hour after the injury. Replantation was accomplished without root surface alteration or root canal intervention. Clinical and radiographic follow-up examinations for over 1 year revealed continued root growth and apical development of the replanted avulsed immature maxillary central incisor with no signs or symptoms of pulpal or periapical pathosis. Excellent outcomes were achieved for periodontal ligament reattachment without removal of the periodontal membrane and pulp revascularization without endodontic intervention.

Keywords: Immature, incisor, pulp, replanted, revascularization

INTRODUCTION

Traumatic dental injuries to the permanent dentition predominantly occur during the 10-year period of 6 to 16 years of age, with a mean age of 11 years and overwhelmingly affect the maxillary incisor teeth (1-8). Dental avulsion, the most severe type of dental traumatic injury, is the disarticulation of a tooth from its socket. The term extra-articulation has also been used to describe this injury, to emphasize that the tooth completely came out of its alveolar socket (9). Tooth avulsion accounts for an average of 8% of all traumatic dental traumatic injuries sustained among different patient populations (1-8). In an extensive investigation of 10,166 traumatically injured permanent teeth in 4,754 patients, 8.8% were avulsions (10).

When the teeth are traumatically avulsed, two essential dental tissues immediately sustain serious injury. The vascular blood supply to the dental pulp is completely severed at the apical foramen, causing the pulp tissue to undergo necrosis and the periodontal ligament attachment at the lamina dura of the alveolar bone socket is separated, causing the periodontal membrane on the root surface cementum to lose viability (11-13).

Replantation of avulsed teeth as soon as possible after avulsion is essential to maintain the viability of the periodontal membrane for reattachment and prevention of replacement root resorption (11, 14, 15). For replanted mature teeth with fully developed root apices, it is also essential that the necrotic pulp tissue be removed in a timely manner after replantation to prevent inflammatory root resorption (16, 17). However, for replanted immature teeth with incomplete root formation
and wide open apices, the pulpal tissue should not be re-
moved, as there is a potential for dental pulp revascularization
(16, 17).

The authors report a case of successful pulp revasculariza-
tion with continued root growth and apical development of
an avulsed immature permanent maxillary central incisor re-
planted over 1 hour after traumatic avulsion in an 8-year-old
child and followed for over 1 year.

CASE PRESENTATION

History
An 8-year-old girl and her mother arrived at a hospital den-
tal clinic with the child’s front tooth wrapped in a wet paper
towel. The tooth had been completely “knocked-out of the
mouth” in a sledding accident that occurred over 1 hour ago,
as estimated by the mother. Medical history revealed that the
child was in good general health with no known allergies, was
not taking any medications and had an up-to-date tetanus im-
umunization.

Examination
The child was alert and responsive but somewhat apprehen-
sive. The completely intact avulsed immature permanent
maxillary central incisor with approximately two thirds of its
normal root length formed was placed in physiologic saline
and a radiograph of the tooth socket was taken. Clinical oral
examination revealed that the maxillary left central incisor
was missing due to traumatic avulsion. The child was in the
mixed dentition stage of dental development with maxillary
anterior over-jet protrusion and rotated eruption of the right
central incisor. There was a 1-cm labial mucosal laceration and
a contusion of the upper lip. The mother gave informed con-
sent for treatment and replantation of her child’s tooth. Radio-
graphic examination revealed the missing avulsed maxillary
left central incisor, the empty alveolar socket with no fractures
and the presence of the adjacent intact immature maxillary
incisors (Figure 1).

Treatment
Local anesthesia was administered by supra-periosteal labial
infiltration of one cartridge lidocaine 2% 1:100,000 epineph-
rine. The alveolar socket was irrigated with physiologic sa-
line, the blood clot removed and bleeding encountered. The
avulsed incisor was replanted into its socket and splinted with
0.032-gauge arch wire bonded to the adjacent incisors with
composite resin. The mucosal lip laceration was sutured with
three interrupted 04 silk sutures. Penicillin VK 500 mg q8h for
5 days and Tylenol 325 mg q6h prn were prescribed and home
care instructions given.

Follow-up
One week after replantation, the patient was asymptomatic.
Clinical examination revealed that the maxillary incisors and
splint were stable, the maxillary labial alveolar mucosa was
normal and the gingival attachment around the maxillary left
central incisor was well adapted (Figure 2). Radiographic exam-
ination revealed that the replanted and splinted maxillary left
central incisor was in normal position in its socket (Figure 3).
The lip sutures were removed and the laceration was healing. Five weeks after replantation, the patient was asymptomatic and the splint was removed. Clinical examination revealed that the lip laceration had completely healed, the alveolar mucosa was normal with no swelling or tenderness to palpation, and the maxillary incisors were stable with normal functional mobility, intact gingival attachments and no pain on percussion (Figure 4). Pulp vitality tests were negative for the maxillary incisors, a usual finding for developing immature teeth. Radiograph examination revealed normal alveolar bone with no periapical or periradicular radiolucencies (Figure 5). Five months after replantation, all clinical examination parameters for the mucogingival tissues and the maxillary incisors were normal; however, pulp vitality tests continued to be inconclusive. Radiograph examination revealed progressive root growth and apical development of the maxillary incisors with normal-appearing root surfaces and alveolar bone (Figure 6). Fifteen months after replantation, while the patient was undergoing orthodontic treatment for her Class II malocclusion, clinical examination revealed that the maxillary incisors were asymptomatic without pain on percussion or tenderness to palpation and had normal functional tooth mobility, intact gingival attachments and positive pulp vitality tests. Radiographic examination of the replanted left central incisor revealed continued root growth and apical development consistent with that of the right central incisor, normal periapical and periradicular bone, slight narrowing of the root canal and mild partial pulp calcification (Figure 7).
DISCUSSION
Based on current guidelines for the management traumatic dental injuries, avulsed immature teeth should be replanted and monitored over time for pulp revascularization (16, 17). In a classic study of 110 avulsed human teeth stored in wet and dry environments for extra-alveolar time periods of up to 2 hours, it was found that 57% of the immature teeth that were replanted after accidental avulsion clinically and radiographically showed a pulpal revascularization response and except for one, all showed no root resorption (18). It should be mentioned, however, that the revascularized pulps later exhibited partial pulp calcification. (18, 19).

In a comprehensive four-part clinical study on the prognosis of 400 replanted avulsed incisor teeth in 322 patients, whose ages ranged from 5 to 52 years with a mean age of 14 years and a median age of 11 years, and who were prospectively followed for pulpal and periodontal healing over a 23-year period with a mean observation period of 5 years, it was found that 70% of the teeth were retained (20-23). Pulpal healing among all 400 teeth was 8%, whereas pulpal healing among 94 of 110 immature teeth, in which pulpal revascularization was deemed to be possible, was 34% and increased with decreased root development for teeth in the very early stages of root formation with wide open apices (21). It was determined, according to the root formation stages (1, root length ¼; 2, root length ½; 3, root length ¾; 4, root length complete; 5, apex ½ closed and 6, apex completely closed) as described by Moorrees (24), that the rate of pulp revascularization was: 16% at stage 5, 35% at stage 4, 40% at stage 3 and 60% at stage 2 (21). It was also found that among 28 avulsed immature teeth replanted at stages of incomplete root development, 25% showed complete root development, 29% showed partial root development and 46% showed arrested root development (22). With respect to periodontal reattachment among all teeth studied, it was found that periodontal healing with no signs of root resorption occurred in 24%, and periodontal healing with no signs of progressive root resorption occurred in 36% (23). Additionally, the overall rate of periodontal healing was related to the stage of root development and was better for teeth with incomplete apical closure (23).

Four further clinical investigations on the frequency of pulpal revascularization and periodontal reattachment of replanted immature permanent anterior teeth in the developing dentition of children have demonstrated that these teeth had a rea-
sonable prognosis for the retention (25-28). In an assessment of 154 replanted avulsed permanent incisors that correlated pulp revascularization with respect to the width of the apical foramen, the rate of revascularization in the entire sample studied was 8% with a difference between immature teeth (which was 18%) and mature teeth (which was 0%). However, the rate of revascularization was highest at 25% among the group of immature teeth with an apical foramen width of 2 to 3 mm (25). A clinical and radiographic retrospective study of 33 teeth with fully formed root lengths but with open apices at Moorrees (24) stages 5 and 6, replanted within 1 to 3 hours or more after avulsion and followed for up to 5 years, found that only 24% were diagnosed with pulp necrosis and endodontically treated. For those teeth replanted within 1 hour after avulsion, the periodontal healing rate was 67%, whereas for teeth replanted three or more hours after avulsion, 83% had root resorption (26). In an investigation of 103 replanted permanent incisors in different age groups that were examined after being followed for an average of 2.5 years, it was found that pulp revascularization occurred in 41% of the teeth of children, 9% of the teeth of adolescents and 0% of the teeth of adults (27). Also, in a follow-up treatment assessment of 45 replanted avulsed permanent anterior teeth, periodontal healing was found to occur in 63% of teeth with open apices compared to 55% of teeth with closed apices (28).

In light of these clinical studies (25-28), it is clear that pulp revascularization and periodontal reattachment can be considered viable outcomes with favourable prognoses for replanted avulsed immature permanent teeth among children, within the parameters of current guidelines for the management of tooth avulsions (16, 17).

In the clinical case presented, this 8-year-old child, in the mixed dentition stage of dental development, had anterior maxillary over-jet protrusion. This type of malocclusion is considered to be a predisposing factor for traumatic dental injuries (29, 30). Because of the short root lengths of the replanted and adjacent incisors, a standard, functionally flexible composite bonded wire splint was applied and left in place for an extended time period of 5 weeks to ensure adequate stabilization during the healing process (31). In vitro and in vivo investigations that measured the lateral tooth movement of teeth with this type of splint have demonstrated that its immobilization effect did not exceed normal tooth firmness during use and that it provided a degree of tooth mobility similar to non-splinted teeth (32-35). Therefore, the extended splinting time for this immature tooth with a short root and a wide, open apex was reasonable.

Although vital pulpal responses were elicited for all of the maxillary incisors at the last recall examination, the pulpal vitality responses at examinations during the earlier follow-up periods were inconclusive. Findings of this type for pulp vitality testing are not uncommon for traumatized teeth, as there can be a temporary loss of sensory nerve function which can return later even in replanted avulsed immature teeth (36-40). Also, pulp vitality test results with immature teeth can be misleading because full development of the Plexus of Raschkow and full pulpal innervation with A-delta nerve fibers takes place after root formation has been completed (41-43). Radiographic examination at the last recall assessment 1 year after avulsion revealed that root growth and apical development of the replanted maxillary left central incisor had progressed and was comparable to that of the adjacent maxillary central incisor (Figure 7). It was also observed that there was a slight narrowing of the root canal and a mild degree of partial pulp calcification of the replanted left central incisor. However, pulp calcification of this type is not an unusual finding following replantation of avulsed immature permanent teeth and is not considered to be an adverse sequela for long-term periapical health (18, 19, 25, 44).

At the time of a traumatic event, the out-of-mouth time is often difficult to exactly determine and is usually an approximate estimation. In the case presented, the extra-alveolar period from the time of the accident to the time that the patient arrived for treatment was approximately estimated at over 1 hour. The tooth was kept wrapped in a moist environment during that period and then placed in physiological saline until it was replanted. Treatment guidelines are extremely important in providing the clinician with the most current evidence-based information for the management of traumatic dental injuries and form the basis for treatment decisions (45). The treatment guidelines for the replantation of avulsed immature teeth with an extra oral time of less than 1 hour recommend immediate replantation, whereas the guidelines for teeth with an extra-oral time of more than 1 hour recommend one or more of the following procedures: removal of the periodontal ligament, soaking in 2% sodium fluoride and possibly performing root canal treatment prior to replantation (16, 17). Under the circumstances of this particular case, it was determined that the guidelines for the replantation of immature teeth with an extra oral period of less than 1 hour were appropriate. Therefore, the tooth was replanted without disrupting the periodontal membrane or disturbing the dental pulp, with excellent outcomes for periodontal ligament reattachment and pulpal revascularization. A systemic antibiotic was prescribed, consistent with the recommended treatment guidelines (16, 17) and based on evidence that the presence of microorganisms hindered pulp revascularization (46) and that systemic antibiotics administrated at the time of replantation prevented inflammatory root resorption (47).

CONCLUSION
This clinical case demonstrated that an immature maxillary permanent central incisor, replanted under less than optimal conditions, underwent pulp revascularization and periodontal reattachment and was retained in a state of health. In the treatment of children with traumatic avulsions of immature
permanent anterior teeth, when extra-alveolar time periods and storage media conditions are not optimal, consideration should be given to replantation without root surface alteration or root canal intervention. Treatment decisions should be patient-centered and made in consideration of accepted evidence-based treatment guidelines, the clinical circumstances presented at the time of the injury, the clinical judgement of the attending dentist and the dental and oral health needs of the patient.
